## 1. Introduction

Ever since Siri was launched by Apple in 2011, people outside the world of science began to have a rough idea of what artificial intelligence is. While these topics have gained more and more popularity since then and are often one of the main topics at global conferences, the application potential must be considered realistically. Although the application of neural networks in the just mentioned natural language processing (NLP) is reasonable, the opinion is split in the application in the field of financial time series. Since a large part of movements of financial instruments are based on white noise and thus have almost no dependency structure, the implementation of a meaningful method is challenging. Likewise, an integration of neural networks only makes sense if a profit can be achieved - for instance, in the case of financial data as a result of trading. This paper will deal exactly with this topic. Simple feedforward networks (FFN) and recurrent neural networks (RNN, LSTM, RNN) will be trained. Then, based on the trained networks, a simple trading strategy will be applied to assess whether it adds value to a potential investor.

## 2. Theory

### 2.1. Multilayer perceptron (MLP)

Multilayer perceptrons (MLP) are widely used feedforward neural network models and make usage of the backpropagation algorithm. They are an evolution of the original perceptron proposed by Rosenblatt in 1958 [1]. The distinction is that they have at least one hidden layer between input and output layer, which means that an MLP has more neurons whose weights must be optimized. Consequently, this requires more computing power, but more complex classification problems can be handled [2]. Figure 1 shows the structure of an MLP with  $n$  hidden layers. Compared to the perceptron, it can be seen that this neural network consists of an input layer, one or more hidden layers, and an output layer. In each layer, there is a different number of neurons, respectively nodes. These properties (number of layers and nodes) can be summarized with the term ‘network architecture’ and will be dealt with in this paper.

Figure 1: Schematic diagram of a multilayer perceptron

Every neural network has an input layer, which consists of one or more nodes. This number is determined from the training data and tells us how many features should be delivered to the neural network. In the case of Ethereum (ETH) prices, we could use today's price and the prices of the last 10 days (lags 1-10), so the input layer would consist of 11 nodes. Some configurations also require a bias term to adjust the output along with the weighted sum, which is also added to the input layer. Similarly to the input layer, each neural

network has exactly one output layer. This can consist of one or more nodes. In this thesis, MLP is used as a regressor and therefore only one neuron is needed in this layer.

In between are the hidden layers, whose number and size can be configured as desired. The challenge is to find an optimal and efficient configuration without causing overfitting of the training data. The number of hidden layers depends primarily on the application area of the neural network. For example, working with image recognition would require more layers since the image file is broken down into individual pixels. Subsequently, the layers are used to optimize from rough outlines to the smallest detail. In our research, we came across several methods or ‘rules of thumb’ to optimize the model. A frequently suggested method is explained by Andrej Karpathy (director of the AI department of Tesla, Inc.). His GitHub entry recommends the approach of starting with a model that is too large that causes overfitting. Subsequently, the model is reduced by focusing on increasing training loss and improving validation loss [3].

## 2.2. Recurrent neural networks (RNN)

Recurrent neural networks (RNN) are a further development of conventional neural networks. While MLP use new inputs  $x_i$  in each epoch, RNN also use sequential data  $h_i$  in addition to  $x_i$ . This sequential data are called hidden states and result from the previous runs. This has the advantage that historical information stemming from past predictions is included for the prediction for  $t+1$ . This effect can be intuitively explained by an example in which the flight path of a scheduled flight is predicted using RNN. When predicting the exact location (coordinates) of a plane, it is of great advantage to know the location at  $t-1$  and to derive the flight direction from it. With the inclusion of this information, the target area can be narrowed down, which optimally leads to more accurate results. The same principle is used in applications like machine translation and speech recognition, where the result (here possibly letter or word) of the last epoch plays a big role for the next prediction [4].

Figure 2: Process sequences of different applicances of RNN.

Figure 2 shows different process sequences of the RNN, which vary depending on the field of application. The red rectangles at the bottom represent the number of inputs. Similarly, the blue rectangles represent the outputs that come out of the RNN. The term ‘many’ refers to  $> 1$  and is illustrated with three rectangles in the figure. The green ones represent the hidden states  $h_i$  of all time steps and thus can be seen as the memory of the neural network. The green arrows show that the previous hidden state is used as input for the current step. Starting from the left: one-to-many can be used for image captioning (extracting sequence of words from images), many-to-one for sentiment classification from sequence of words, many-to-many for machine translation (sequence of words in one language to sequence of words in another language) and many-to-many for video classification on frame level [5]. For the prediction of the ETH/USD exchange rate in this paper, we deal with the process many-to-one. This method combines information from inputs and hidden states into one single prediction value.

Figure 3: Computational graph of a many-to-one RNN.

$$\begin{aligned} h_i &= f_W(h_{i-1}, x_i) \\ &= \tanh(W_h h_{i-1} + W_x x_i + b) \end{aligned} \quad (1)$$

Equation 1 shows how the hidden states  $h_i$  are calculated at each time step,  $i$  where  $f_W$  is an activation function (here: hyperbolic tangent function),  $h_{i-1}$  is the previous state and  $x_i$  is the input vector at time step  $i$ . In some cases, a bias term  $b$  is added to the parameters.  $W_h$  represents the weight matrix for  $h_i$  with dimension  $(\text{length}(h) \times \text{length}(h))$ . Thus,  $W_x$  is the weight matrix for  $x_i$  with dimension  $(\text{length}(h) \times \text{length}(x))$ .

$$\hat{y}_i = W_y h_i \quad (2)$$

Looking at equation 2,  $y_i$  equals the output and desired prediction of the RNN. The prediction results from the matrix-vector product of the weight matrix  $W_y$  with dimension  $(\text{length}(h) \times \text{length}(y))$  and the hidden states vector  $h$ .

### 3. Methods

This section covers how to define a trading strategy from the trained networks. It is also dedicated to the topic of how the performance is evaluated.

#### 3.1. Data exploration

First, we will explore the the development of ETH over time. Figure 4 shows the price, the logarithmic price and the logarithmic return. The logarithmic price is used to better compare the changes from the price as the relative change becomes visible. The same is true for the log return which shows stationarity. In the first two plots the local peaks are well visible, which reached a then ATH (All-Time High) of USD 1313 in January 2018. It can also be seen that we are in a bull run at the time of writing this paper. In the logarithmized return, it can be seen that the volatility is not constant and thus shows volatility clusters.

Figure 4: Time plot of the price, logarithmized price and logarithmized return based on the price for ETH/USD. Large (crypto) market phase dependencies and volatility persistence are evident.

Continuing with the autocorrelation (ACF) and partial autocorrelation (PACF), we notice a dependency structure in both cases. The ACF plot in figure 5 show that lags 5, 10, 16, 17 and 19 are significantly stronger than just white noise. Similarly, lags 5, 10, 16, 17 and 19 are significant in the PACF plot. This information should be kept in mind when choosing the optimal network architecture of the neural network as it seemingly makes sense to include enough data points.

Figure 5: Autocorrelation and partial autocorrelation of logarithmic return of the ETH/USD-Prices.

Optimization of the ETH with the `auto.arima` function from the package `forecast` indicates that it could be modeled by an ARMA(3,3). However, occasional volatility clustering of the standardized residuals may suggest that model assumptions for the error term (white noise) are possibly violated. Since we are working with neural networks, we will deal with the network architecture next.

### 3.1. Neural Network Architecture

We would like to trade ETH/USD, which is why a trustworthy forecast is desired. Now there are countless ways how to modify neural networks and get different solutions at best. In order to reduce the scope, we limit ourselves to a 6-month in-sample and a 1-month out-of-sample split. First, this shortens the computational work and we can compare different methods and architectures using the same time period. In addition, the split is proposed in [6]. The split can be seen in figure 6, where red is the in-sample and blue is the out-of-sample. The autocorrelation function of the dataset subset shows dependence at lag 5 and 10, which is why we go to a maximum of lag 10 for the input layer.

In addition, we limit ourselves in terms of network architecture. On the one hand, the added value for too large networks is somewhat moderate for time series (source) and on the other hand, this would go beyond the scope of this work. For each network type presented in section 2, network architectures from 1 layer with 1 neuron to 3 layers with 10 neurons each are trained. We thus examine a total of 1100 different neuron layer combinations, with (1) the simplest and (10,10,10) the most complex network. To make a comparison possible, the respective in/out-of sample MSEs and Sharpe ratios are calculated for each network. To mitigate the problem of optimizing the backpropagation algorithm, 100 nets are trained and averaged for each architecture for the feedforward networks (FFN). For the recurrent network types (RNN, LSTM, GRU) only 10 networks per architecture are trained but with 10 epochs each.
