

# The Impact of Network Architecture and Network Type of Neural Networks on Trading Performance

OEKO3 Final Project

Pascal Bühler, Ken Geeler, Philipp Rieser

Spring Semester 2021

## **Abstract**

The use of neural networks and their utility in financial time series is a frequently studied topic. Plain vanilla feedforward neural networks, recurrent neural networks (RNN), gated recurrent unit (GRU) and long short-term memory (LSTM) are applied and compared. The impact of the choice of a specific network type and network architecture (number of layers and neurons) on trading performance is investigated. Using a fixed in-sample and out-of-sample, all possible combinations between the simplest (one layer and one neuron) and the most complex network (three layers and ten neurons) are trained and their trading performance is quantified. This is done for each of the four network types. Still missing = part about performance plots and main Erkenntnis!!!!

## 1. Introduction

Ever since Siri was launched by Apple in 2011, people outside the world of science began to have a rough idea of what artificial intelligence is. While these topics have gained more and more popularity since then and are often one of the main topics at global conferences, the application potential must be considered realistically. Although the application of neural networks in the just mentioned natural language processing (NLP) is reasonable, the opinion is split in the application in the field of financial time series. Since a large part of movements of financial instruments are based on white noise and thus have almost no dependency structure, the implementation of a meaningful method is challenging. Likewise, an integration of neural networks only makes sense if a profit can be achieved - for instance, in the case of financial data as a result of trading. This paper will deal exactly with this topic. Simple feedforward networks (FFN) and recurrent neural networks (RNN, LSTM, GRU) will be trained. Then, based on the trained networks, a simple trading strategy will be applied to assess whether the selection of a specific network architecture in combination with a network type adds value to a potential investor.

## 2. Theory

### 2.1. Multilayer perceptron (MLP)

Multilayer perceptrons (MLP) are widely used feedforward neural network models and make usage of the backpropagation algorithm. They are an evolution of the original perceptron proposed by Rosenblatt in 1958 [1]. The distinction is that they have at least one hidden layer between input and output layer, which means that an MLP has more neurons whose weights must be optimized. Consequently, this requires more computing power, but more complex classification problems can be handled [2]. Figure 1 shows the structure of an MLP with  $n$  hidden layers. Compared to the perceptron, it can be seen that this neural network consists of an input layer, one or more hidden layers, and an output layer. In each layer, there is a different number of neurons, respectively nodes. These properties (number of layers and nodes) can be summarized with the term ‘network architecture’ and will be dealt with in this paper.

Figure 1: Schematic diagram of a multilayer perceptron

Every neural network has an input layer, which consists of one or more nodes. This number is determined from the training data and tells us how many features should be delivered to the neural network. In the case of Ethereum (ETH) prices, we could use today's price and the prices of the last 10 days (lags 1-10), so the input layer would consist of 11 nodes. Some configurations also require a bias term to adjust the output

along with the weighted sum, which is also added to the input layer. Similarly to the input layer, each neural network has exactly one output layer. This can consist of one or more nodes. In this thesis, MLP is used as a regressor and therefore only one neuron is needed in this layer.

In between are the hidden layers, whose number and size can be configured as desired. The challenge is to find an optimal and efficient configuration without causing overfitting of the training data. The number of hidden layers depends primarily on the application area of the neural network. For example, working with image recognition would require more layers since the image file is broken down into individual pixels. Subsequently, the layers are used to optimize from rough outlines to the smallest detail. In our research, we came across several methods or ‘rules of thumb’ to optimize the model. A frequently suggested method is explained by Andrej Karpathy (director of the AI department of Tesla, Inc.). His GitHub entry recommends the approach of starting with a model that is too large that causes overfitting. Subsequently, the model is reduced by focusing on increasing training loss and improving validation loss [3].

The feedforward neural network used in this paper is implemented using the R package ‘neuralnet.’

## 2.2. Recurrent neural networks (RNN)

Recurrent neural networks (RNN) are a further development of conventional neural networks. While MLP use new inputs  $x_i$  in each epoch, RNN also use sequential data  $h_i$  in addition to  $x_i$ . This sequential data are called hidden states and result from the previous runs. This has the advantage that historical information stemming from past predictions is included for the prediction for  $t+1$ . This effect can be intuitively explained by an example in which the flight path of a scheduled flight is predicted using RNN. When predicting the exact location (coordinates) of a plane, it is of great advantage to know the location at  $t-1$  and to derive the flight direction from it. With the inclusion of this information, the target area can be narrowed down, which optimally leads to more accurate results. The same principle is used in applications like machine translation and speech recognition, where the result (here possibly letter or word) of the last epoch plays a big role for the next prediction [4].

Figure 2: Process sequences of different applicances of RNN.

Figure 2 shows different process sequences of the RNN, which vary depending on the field of application. The red rectangles at the bottom represent the number of inputs. Similarly, the blue rectangles represent the outputs that come out of the RNN. The term ‘many’ refers to  $> 1$  and is illustrated with three rectangles in the figure. The green ones represent the hidden states  $h_i$  of all time steps and thus can be seen as the memory of the neural network. The green arrows show that the previous hidden state is used as input for the current step. Starting from the left: one-to-many can be used for image captioning (extracting sequence of words from images), many-to-one for sentiment classification from sequence of words, many-to-many for machine translation (sequence of words in one language to sequence of words in another language) and many-to-many

for video classification on frame level [5]. For the prediction of the ETH/USD exchange rate in this paper, we deal with the process many-to-one. This method combines information from inputs and hidden states into one single prediction value.

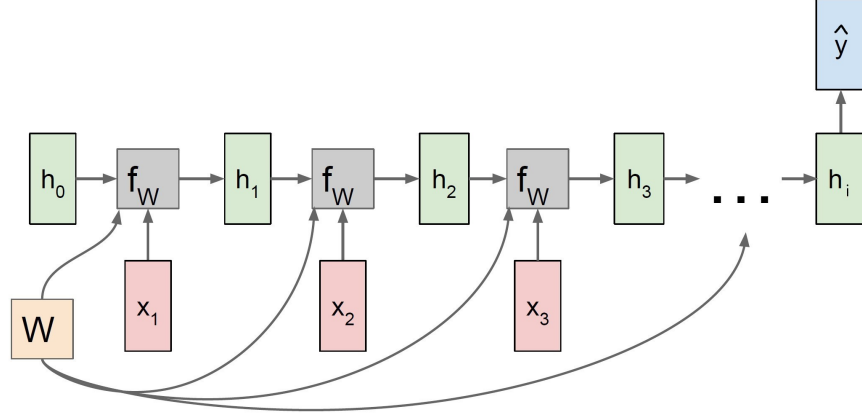

Figure 3: Computational graph of a many-to-one RNN.

$$\begin{aligned} h_i &= f_W(h_{i-1}, x_i) \\ &= \tanh(W_h h_{i-1} + W_x x_i + b) \end{aligned} \quad (1)$$

Equation 1 shows how the hidden states  $h_i$  are calculated at each time step,  $i$  where  $f_W$  is an activation function (here: hyperbolic tangent function),  $h_{i-1}$  is the previous state and  $x_i$  is the input vector at time step  $i$ . In some cases, a bias term  $b$  is added to the parameters.  $W_h$  represents the weight matrix for  $h_i$  with dimension  $(\text{length}(h) \times \text{length}(h))$ . Thus,  $W_x$  is the weight matrix for  $x_i$  with dimension  $(\text{length}(h) \times \text{length}(x))$ .

$$\hat{y}_i = W_y h_i \quad (2)$$

Looking at equation 2,  $y_i$  equals the output and desired prediction of the RNN. The prediction results from the matrix-vector product of the weight matrix  $W_y$  with dimension  $(\text{length}(h) \times \text{length}(y))$  and the hidden states vector  $h$ .

### 2.3. Gated Recurrent Unit (GRU) and Long Short-Term Memory (LSTM)

In summary, recurrent neural networks retain information in memory over time. However, it can be difficult to train standard RNN's to solve problems that require learning long-term dependencies. This is because the gradient of the loss function decreases exponentially with time (vanishing gradient problem). Since the hidden states are overwritten with many time steps, the extensions LSTM and GRU apply an extended concept with separate memory. The weighting functions (the so-called gates) control which information is kept and which may be forgotten.

In the GRU cell, the two gates  $r_t$  and  $z_t$  are implemented, as can be seen in figure 4. Both are weighting functions that influence whether the cell state  $s$  should be updated or the last value is important enough to be kept. The reset gate  $r_t$  decides if the previous hidden state  $s_{t-1}$  should be ignored. The update gate  $z_t$  on the other hand decides if the  $\tilde{s}_t$  should be passed to the next hidden state  $s_t$  [6].

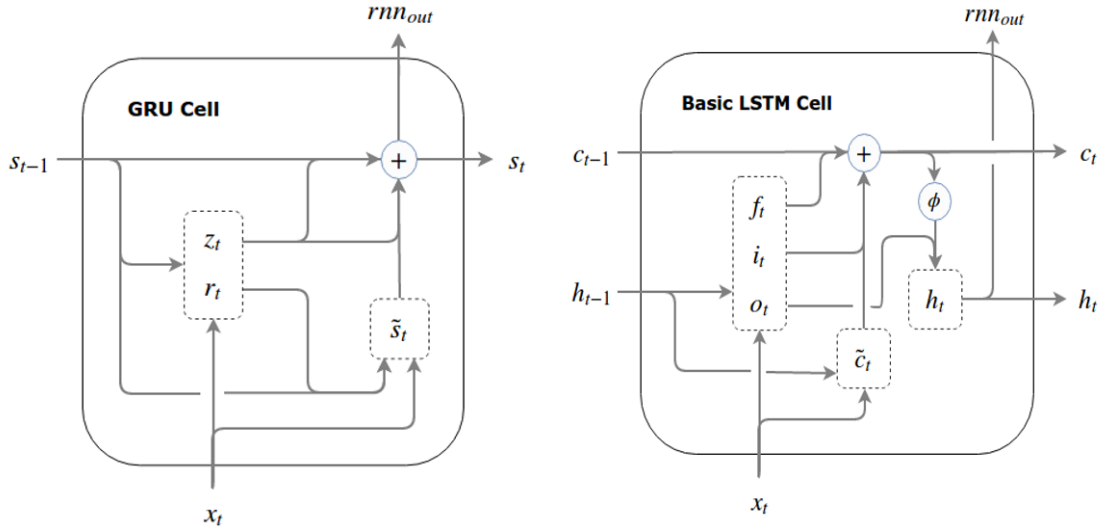

Figure 4: Workflow of a GRU cell (left) and LSTM cell (right).

In contrast to the GRU cell, the LSTM cell has additional gates. They are used to control when information enters memory, when it is output, and when it is forgotten. This architecture allows them to learn longer-term dependencies. The input gate  $i_t$  takes in new information  $x_t$  and the previous hidden state  $h_{t-1}$ . The forget gate  $f_t$  gets the same information as input and controls how much information should be kept up to which value. Information from the previous cell state  $c_{t-1}$ , the forget gate  $f_t$ , the input gate  $i_t$  and  $\tilde{c}_t$  are passed on to the next cell state  $c_t$ . Finally, the output gate  $o_t$  influences the next hidden state  $h_t$  as well as the output of the cell [6].

The three recurrent neural networks presented are implemented using the R package `rnn`.

### 3. Methods

This section covers how to define a trading strategy from the trained networks. It is also dedicated to the topic of how the performance is evaluated.

#### 3.1. Data exploration

First, we will explore the the development of ETH over time. Figure 5 shows the price, the logarithmic price and the log return. The logarithmic price is used to better compare the changes from the price as the relative change becomes visible. The same is true for the log return which shows stationarity. In the first two plots the local peaks are well visible, which reached a then ATH (All-Time High) of USD 1313 in January 2018. It can also be seen that we are in a bull run at the time of writing this paper. In the log return, it can be seen that the volatility is not constant and thus shows volatility clusters.

Figure 5: Time plot of the price, logarithmized price and log return based on the price for ETH/USD. Large (crypto) market phase dependencies and volatility persistence are evident.

Continuing with the autocorrelation (ACF) and partial autocorrelation (PACF), we notice a dependency structure in both cases. The ACF plot in figure 6 show that lags 5, 10, 16, 17 and 19 are significantly stronger than just white noise. Similarly, lags 5, 10, 16, 17 and 19 are significant in the PACF plot. This information should be kept in mind when choosing the optimal network architecture of the neural network as it seemingly makes sense to include enough data points.

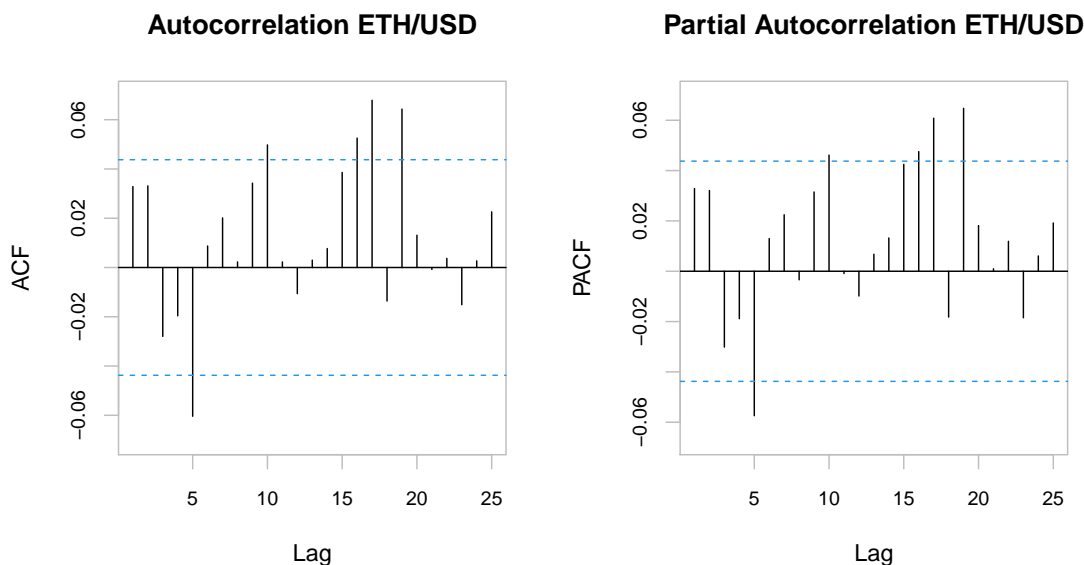

Figure 6: Autocorrelation and partial autocorrelation of log return of the ETH/USD-Prices.

Optimization of the ETH log return with the `auto.arima` function from the package `forecast` indicates that it could be modeled by an ARMA(3,3). However, occasional volatility clustering of the standardized residuals may suggest that model assumptions for the error term (white noise) are possibly violated. Since we are working with neural networks, we will deal with the network architecture next.

### 3.1. Neural Network Architecture

The aim is to trade ETH/USD, which is why a trustworthy forecast is desired. There are countless ways how to modify neural networks and get different solutions at best. In order to reduce the scope, we limit ourselves to a 6-month in-sample and a 1-month out-of-sample split, as G. Sermpinis and A. Karathanasopoulos proposed [7]. This shortens the computational work and we can compare different methods and architectures using the same time period. The split can be seen in figure 7, where red is the in-sample and blue represents the out-of-sample. The autocorrelation function of the data subset shows dependence at lag 5 and 10, which is why we go to a maximum of lag 10 for the input layer.

In addition, we limit ourselves in terms of network architecture. On the one hand, the added value for too large networks is somewhat moderate for time series (source) and on the other hand, this would go beyond the scope of this work. For each network type presented in section 2, network architectures from 1 layer with 1 neuron to 3 layers with 10 neurons each are trained. We thus examine a total of 1100 different neuron layer combinations, with (1) the simplest and (10,10,10) the most complex network. To make a comparison possible, the respective in/out-of sample MSE's and Sharpe ratios are calculated for each network. To mitigate the problem of optimizing the backpropagation algorithm, 100 nets are trained and averaged for each architecture for the feedforward networks (FFN). For the recurrent network types (RNN, LSTM, GRU) only 10 networks per architecture are trained but with 10 epochs each.

Figure 7: Subset of 7 months. Log returns on the left, acf on the right.

Figure 7 visualizes the MSE's for in- and out-of sample of all neuron-layer combinations for all 4 network types. The network architectures are separated by color. On the far left in red, are the networks with only one layer. We have only 10 networks with one layer, which is why this area is very small. In comparison, in the purple part are all networks with a 3-layer architecture.

Noticeable in black are the MSE's of the FFN. They are very different from the 3 recurrent types. We can see strongly how the network architecture influences the error terms. With increasing complexity, the error in the in-sample decreases but increases in the out-of-sample. This indicates an overfitting of the backpropagation algorithm. It is remarkable that the in-sample MSE with the architecture (10,10) results in a much smaller error than a very simple model with three layers such as (1,1,1). The out-of-sample MSE improves drastically by using an architecture of (1,1,1). In this case, the addition of another layer adds value despite the small number of neurons.

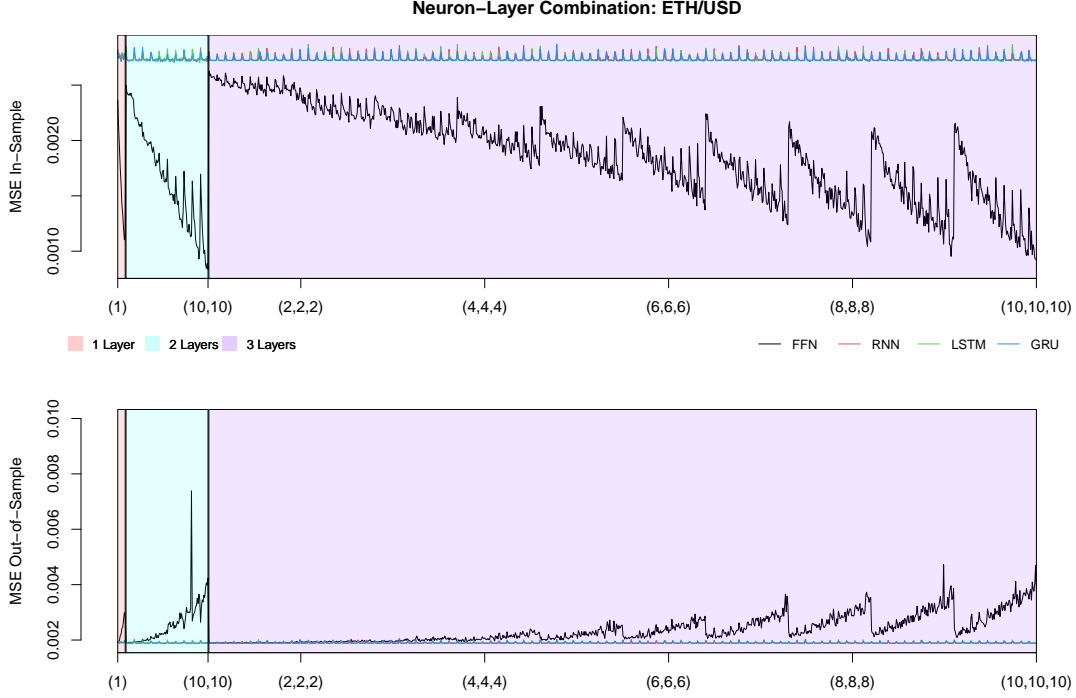

Figure 8: In and out-of sample MSE of all neural networks. For FFN, 100 networks were averaged in each case. For the recurrent ones, only 10 were averaged.

It is difficult to determine an optimal architecture based on the MSE. Simply taking the smallest value would not be effective. Small in-sample MSE values appear with complex networks, which tend to overfitting out-of-sample. Additionally, the 3 recurrent types are visualized. You can hardly distinguish them from each other since their behavior is rather similar. Nevertheless, you can see how all 3 varies around a fixed value. For a better interpretability only the RNN types are visualized in the following figure 9.

Here you can see the structure of the recurrent networks a little better. There is no pattern like in the FFN, the MSE's have no inverse correlation between in- and out-of sample. There is a certain value that is not undercut. The MSE cannot get better than a certain value. The spikes that occur uniformly are striking. An examination of the results showed that the spikes appear with certain network architectures. If only 1 or 2 neurons were specified in each case in the last layer, then this leads to this strange spike. In the attachment in figure 13, the neuron-layer combinations with 1 or 2 neurons in the last layer have been removed. There you can see how the spikes have disappeared. Keep in mind, however, that the differences between apparent convergence and a spike are not very large. Furthermore, only 10 networks per combination were trained. This structure could possibly look weakened if one would increase the number of networks.

Figure 9: In and out of sample MSE of the 3 different recurrent network types.

Nevertheless, we cannot use this visualization to determine an optimal network architecture based on the MSE. Regardless of the complexity, one achieves approximately the same error.

Figure 10: In and out-of sample Sharpe ratios of all neural networks.

The architecture which we previously defined, are now used to compare against each other. Due to the random component in all the nets we chose a minimum of 100 nets to find an appropriate average.

This procedure is done for ffnn, gru, lstm and also rnn. The results for each net can be found in the [attachement](#).

In figure 11 the average performance for ffnn is visualized in red and the benchmark “buy and hold” is in black. Notable is for the most nets, the performance is above zero, that might be due to the strong upward trend in the data. For an longer out of sample, the distribution of the N nets around the mean, would most likely look more symmetric than it does for only this 30-day out of sample.

For the GRU LSTM and RNN (plots in [attachement](#)) nets performance seems similar as seen in figure 10 converging to buy and hold.

- FFN (1, 4)
- RNN (7)
- LSTM (9, 8, 2)
- GRU (8, 9)

Figure 11: FF out of sample

## 4. Results

When all 4 nets are compared against Buy and Hold in figure 12, we observe that the feed forward net performs slightly better than buy and hold, whilst the other 3 nets are not better or even equal. When we look closer the decision of feedforward in (Letter A 12) is crucial to the performance. Further the decision in (Letter B 12) almost brought the performance back to buy and hold.

From this Behavior it is clear that the benefit in the performance is random.

Figure 12: Performance all

## 5. Conclusion

The application of neural networks to financial time series is a well-studied topic. We use and compare feedforward neural networks, recurrent neural networks (RNN), gated recurrent unit (GRU), and long short-term memory (LSTM). The effect of network type and network architecture on trading performance is analyzed. All possible combinations between the simplest (one layer and one neuron) and the most complex network (three layers and ten neurons) are trained 100 times each and their average trading output is evaluated.

When comparing the network architectures, it can be observed that with FFN the overfitting increases as the number of neurons increases. The same phenomenon cannot be observed to the same extent for RNN, GRU and LSTM. Presumably, there is a numerical problem with the optimization algorithm in the three types of RNN.

Looking at the trading performance, it can be seen that the cumulative returns converge to buy-and-hold in the most optimal case. Although the performance of FFN turns out better than the three competitors, this is most likely a random event and will be different for other time frames.

The advantage of recurrent neural networks is that they receive information from the last step. While this can be a great advantage in many applications, there is no benefit from them in our method. Since the lagged log returns are used as input, in principle historical information is also available to the FFN. Furthermore, the usefulness of long-term memory is also very limited, as it is not suitable for detecting effects in noisy data.

Based on the points mentioned, we see the following opportunities to further develop this Thesis:

- Instead of the R Package ‘rnn’ used, alternatives could be used, such as ‘keras.’ This could possibly help to explain why the RNN, GRU, and LSTM optimizations behaved so strangely.
- The behavior of the neural networks was only considered for a certain time period. These 6+1 months do not represent enough information about an asset class at all.
- Lagged log returns were always used as input in all cases. It could be examined in a further step whether adding more explanatory variables would provide added value. In particular, known indicators of technical analysis, such as a smoothing moving average or the relative strength index (RSI).

In recapitulation of the results we conclude that RNN GRU and LSTM bring no further Benefit in forecasting of financial timeseries.
